

# Evaluating Measurement Quality of Microfluidic Cell-based Assays

## Objective

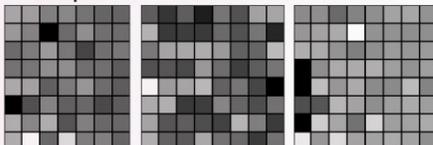

Microfluidic technologies show promise as miniaturized, portable platforms for cell assays, but must be tested to establish confidence of within-device consistency, assurance of day-to-day reproducibility, and clear understanding of how experimental conditions may affect outcomes. As an example, we assessed repeatability in a 64-chamber microfluidic device and measured reproducibility in devices prepared on different days, tested robustness using different illumination sources and reservoir-to-device tubing choices, determined performance across a range of cell loading densities, and compared results from microfluidic devices and larger volume traditional assays.

## Impact and Customers

Our work establishes metrics for measurement quality and reproducibility for cell-based assays within microfluidic devices. Many novel microfluidic devices are being created that permit new measurements or enable new biological functions to be tested; however, characterizations necessary to benchmark the quality and reproducibility of these novel systems are often lacking. Companies that hope to market new instruments and products associated with medical diagnostic and therapeutic applications will require methods to validate the capabilities of these nascent technologies. We published a framework for cell-based measurements in microfluidic devices in *Analytical Chemistry* in 2011. A follow-up study was published in *Lab on a Chip* (2012). Both the FBI and the Bioterrorism Response Laboratory at the Massachusetts Department of Public Health are interested in using this assay for analysis of ricin activity.

## Approach

Microfluidic devices were constructed from polydimethylsiloxane (PDMS) using standard techniques. We designed a simple test bed device with a single inlet and a large number of chambers. The inlet channel branches into eight columns of chambers, and each column contains eight 1.1 mm diameter chambers for a total of 64 chambers. African green monkey kidney epithelial (Vero) cells transfected to express green fluorescent protein (GFP) were loaded into the device to create a gradient of cell densities across the columns of chambers, thus enabling us to test whether cell density had any effect on the assay readout and to determine measurement confidence limits as a function of cell density. We studied GFP expression in the cells with quantitative time-lapse fluorescence microscopy, monitoring the rate at which GFP degrades in cells after they are treated with a reversible ribosome inhibitor, cycloheximide (CHX). The rate of decay of GFP fluorescence in cells is a measure of the effect of CHX, which blocks protein synthesis. The GFP decay rates upon CHX injection in microfluidic devices were compared with results from larger scale culture conditions of cells in 35 mm polystyrene dishes and in dishes coated with PDMS. Cell proliferation and migration rates were calculated from single-cell tracking measurements.

## Accomplishments

We addressed the robustness of the microfluidic assay by repeating experiments under conditions that might change the quality of the assay. Despite the potential toxic effects of tubing leachables and increased variability in data collected with mercury arc lamp illumination, we found no significant difference in the time course of GFP decay in response to CHX (mean GFP decay time constant of 240 min with standard deviation of 13 min). The measurements of GFP decay under different conditions had small within-experiment variations: the maximum coefficient of variation (CV) was 14%. From the ranges of cell density plated in the microfluidic chambers, we determined that a sample of at least 100 cells (167 cells/mm<sup>2</sup>) was necessary to estimate the GFP degradation rate for a population such that the uncertainty due to sampling is less than the uncertainty due to fitting (Figure 1).

We also compared the microfluidic results to results from the assay performed under larger volume conditions and found simi-

lar measurements of GFP decay rate constants. However, the confidence bounds for the larger scale conditions were approximately twice as broad as the confidence bounds for the microfluidic measurements of GFP decay. This finding indicates that, for a given number of cells, microfluidic devices provide a higher level of confidence in the measurement of CHX-induced GFP decay. This result was primarily due to lower fluorescence background in the microfluidic devices, which have inherently lower autofluorescence than polystyrene and which contain less autofluorescent cell culture medium.

Further analysis of the proliferation and migration data illustrate that some cell behaviors within microfluidic devices did differ from larger scale culture conditions.

The cells in the microfluidics experiments were determined to have nearly three-fold slower proliferation rates, yet migration rates were significantly faster than cells cultured in dishes. Follow-up imaging studies suggest that differences in cell behavior may be primarily caused by differences in surface chemistry. Whereas the tissue culture polystyrene (TCPS)- and PDMS-coated dishes were hydrophobic, PDMS in the microfluidic devices was treated with oxygen plasma to bond the devices together, which rendered the surfaces hydrophilic. Using fluorescently labeled fibronectin, we found that cells in the microdevices and on plasma-treated PDMS in dishes were able to rearrange the fibronectin (Figure 2). These data are particularly enlightening in microfluidics research, where surface chemistries are not well controlled, yet differences in cell behavior are often noted.
